We report on the updated theoretical predictions for the width difference $\Delta \Gamma_s$ and the flavor-specific CP asymmetry $a_{fs}$ in the $B_s - \bar{B}_s$ mixing. Working at leading power in the Heavy Quark Expansion we evaluated all previously unknown two-loop contributions to this observable, which marks an important step in the task of reducing uncomfortably large scale uncertainties stemming from uncalculated QCD corrections. Our new Standard-Model prediction for the ratio of the width and mass differences in the $\overline{\text{MS}}$ scheme reads $\Delta \Gamma_s/\Delta M_s = (5.20 \pm 0.69) \cdot 10^{-3}$.
1. Introduction

Modern flavor physics is a rich field for theoretical investigations that encompass not only model building and precision fits but also higher order perturbative calculations. The latter are especially important for observables that are well accessible to experimental measurements and feature small uncertainties due to large amounts of collected data and well understood systematic errors. One of the well-known sources for such observables is the mixing of neutral $B$ mesons. The $B_s - \bar{B}_s$ oscillations described via

$$i \frac{d}{dt} \begin{pmatrix} |B_s(t)\rangle \\ |\bar{B}_s(t)\rangle \end{pmatrix} = \left( \hat{M} - \frac{i}{2} \hat{\Gamma} \right) \begin{pmatrix} |B_s(t)\rangle \\ |\bar{B}_s(t)\rangle \end{pmatrix}, \quad \text{with} \quad \hat{M} = \begin{pmatrix} M_{11} & M_{12} \\ M_{12}^* & M_{22} \end{pmatrix}, \quad \hat{\Gamma} = \begin{pmatrix} \Gamma_{11} & \Gamma_{12} \\ \Gamma_{12}^* & \Gamma_{22} \end{pmatrix}$$

(1)

allow us to extract three physical quantities that can be calculated using quantum field theoretical methods. Diagonalizing the matrices $\hat{M}$ and $\hat{\Gamma}$ we can introduce the width and mass differences between mass eigenstates, $\Delta \Gamma_s$ and $\Delta M_s$ respectively, as well as the CP asymmetry in flavor-specific decays, $a_{fs}$. More explicitly, we have

$$\Delta M = M_H - M_L \approx 2|M_{12}|, \quad \Delta \Gamma = \Gamma_L - \Gamma_H \approx 2|\Gamma_{12}|\cos(\phi_{12}), \quad a_{fs} = \frac{\Gamma_{12}}{M_{12}}\sin(\phi_{12}), \quad (2)$$

where we neglected corrections of order $O(|\Gamma_{12}|^2/|M_{12}|^2)$ and used that

$$M_{12} = |M_{12}|e^{i\phi_M}, \quad \Gamma_{12} = |\Gamma_{12}|e^{i\phi_\Gamma}, \quad \cos(\phi_\Gamma - \phi_M) = -\cos(-\pi + \phi_\Gamma - \phi_M) \equiv -\cos(\phi_{12}). \quad (3)$$

Notice that while $\phi_\Gamma$ and $\phi_M$ depend on phase conventions (e.g. for the CKM matrix), $\phi_{12}$ is a physical CP-violating phase.

Precision flavor observables are very important for new physics searches due to their sensitivity to possible virtual Beyond Standard Model (BSM) particles appearing in the loops. In this respect $\Delta \Gamma_s$ and $\Delta M_s$ are of complementary nature: The former would deviate from its SM value in the case of light particles with masses below the electroweak scale, while the latter could help to find heavy (multi-TeV) degrees of freedom. Furthermore, one may also consider the ratio of both quantities $\Delta \Gamma_s/\Delta M_s$ which has the nice property of being independent of the CKM matrix element $V_{ts}$, while each observable by itself is proportional to $|V_{ts}|^2$. This allows us to circumvent existing issues related to the exclusive and inclusive determinations of $|V_{cb}|$, which is the main ingredient for obtaining $|V_{ts}|$. In addition to that, most hadronic uncertainties cancel from the ratio. Hence, better theoretical predictions for $\Delta \Gamma_s$ that is conventionally regarded as a SM precision probe can readily improve the limits on new physics from $\Delta M_s$.

Experimental measurements for these two quantities resulted in

$$\Delta M_s^{\text{exp}} = (17.7656 \pm 0.0057) \text{ ps}^{-1} \quad [1],$$

$$\Delta \Gamma_s^{\text{exp}} = (0.082 \pm 0.005) \text{ ps}^{-1} \quad [2-8],$$

(4)

(5)

Theoretical predictions for $\Delta \Gamma_s$ [9–16] are still far away from the per cent level accuracy, which should motivate the theorists to improve their calculations. In the framework of the heavy-quark expansion (HQE), the calculation of $\Delta \Gamma_s$ can be understood as a double series in the strong coupling $\alpha_s$ and the ratio $\Lambda_{QCD}/m_b$. Theorists have improved their calculations over the past years, but they are still far from the experimental results. This motivates the need for better theoretical calculations.
A sizable reduction of theoretical uncertainties requires two ingredients. On the one hand, at leading order (LO) in the $\Lambda_{\text{QCD}}/m_b$-expansion one needs to evaluate all the relevant QCD corrections at next-to-next-to-leading order (NNLO) in $\alpha_s$. On the other hand, it is also necessary to consider next-to-leading order (NLO) $\alpha_s$ corrections at NLO in the $\Lambda_{\text{QCD}}/m_b$-expansion. The main goal of our project is to address the former class of corrections i.e. to perform relevant two- and three-loop calculations at leading power.

2. Calculation

The essence of our $\Delta \Gamma_s$ calculation is the matching between two effective theories that describe the $\Delta B = 1$ and $\Delta B = 2$ processes. In the basis of [17] our effective Hamiltonian $\mathcal{H}_{\text{eff}}^{[\Delta B=1]}$ reads

$$
\mathcal{H}_{\text{eff}}^{[\Delta B=1]} = \frac{4G_F}{\sqrt{2}} \left[ -\lambda_s^u \left( \sum_{i=1}^6 C_i Q_i + C_8 Q_8 \right) - \lambda_u^s \sum_{i=1}^2 C_i (Q_i - Q_i^u) \right] + V_{us} V_{cb} \sum_{i=1}^2 C_i Q_i^{cu} + V_{cs} V_{ub} \sum_{i=1}^2 C_i Q_i^{uc} + \text{h.c.},
$$

(6)

where we refer to [17] for the definitions of the current-current operators $Q_{1-6}$, four-quark penguin operators $Q_{7-8}$ and the chromomagnetic penguin operator $Q_8$. The $Q^{u,c,u,c}_{1-2}$ versions of $Q_{1-2}$ are obtained by replacing the two $c$ quarks inside the operator by two $u$ quarks or a combination of a $c$ and a $u$ quark respectively. Explicit expression for these operators can be found e.g. in [18]. Other quantities appearing in the effective Hamiltonian comprise the Fermi constant $G_F$, CKM matrix elements $V_{ij}$ and $\lambda_s^u = V_{us}^* V_{cb}$. Then, $C_i$ denote the Wilson coefficients of the $\Delta B = 1$ effective theory calculated from the matching to SM, where all degrees of freedom heavier than the $b$ quark mass $m_b$ have been integrated out. Eq. (6) contains renormalized physical operators. In the renormalization and regularization procedure one further encounters unphysical operators such as evanescent operators $E[Q_i]$ [19, 20]. Higher loop calculations involving evanescent operators become highly nontrivial when both ultraviolet and infrared poles are regularized dimensionally using the same $\varepsilon$ from the spacetime dimension $d = 4 - 2\varepsilon$. Fortunately, the prescription for NLO calculations explained in [21] can be straightforwardly generalized to NNLO. For further details on the topic we refer to [16].

Let us now turn to the other side of our matching calculation. To calculate $\Gamma_{12}$ we need to consider two insertions of $[\Delta B] = 1$ effective Hamiltonians with proper time-ordering and extract the absorptive part thereof. This bilocal matrix element can be simplified using Heavy Quark Expansion (HQE) [22–31], which yields [12]

$$
\Gamma_{12} = -(\lambda_s^u)^2 \Gamma_{12}^{cc} - 2\lambda_s^u \lambda^s \Gamma_{12}^{uc} - (\lambda_s^u)^2 \Gamma_{12}^{uu},
$$

(7)

with

$$
\Gamma_{12}^{ab} = \frac{G_F^2 m_b^2}{24\pi M_{\text{Bs}}} \left[ H^{ab}(z) \langle B_s | Q | \bar{B}_s \rangle + \bar{H}^{ab}(z) \langle B_s | \bar{Q}_s | \bar{B}_s \rangle \right] + \mathcal{O}(\Lambda_{\text{QCD}}/m_b),
$$

(8)

where $z \equiv m_c^2/m_b^2$ and

$$
Q = \bar{s}_i \gamma^\mu (1 - \gamma^5) b_i \bar{s}_j \gamma_\mu (1 - \gamma^5) b_j, \quad \bar{Q}_s = \bar{s}_i (1 + \gamma^5) b_j \bar{s}_j (1 + \gamma^5) b_i,
$$

(9)
having labels $i,j$ that denote the quark field color indices. The matching coefficients $H^{ab}(z)$ and $\tilde{H}^{ab}_S(z)$ constitute the main goal of our perturbative calculations. Insertions of different operators on the $|\Delta B|=1$ side of the matching and especially QCD corrections to the corresponding Feynman diagrams generate new contributions to $H^{ab}(z)$ and $\tilde{H}^{ab}_S(z)$. Their knowledge is crucial to the task of improving the theory prediction for $\Delta \Gamma_S$.

In the actual calculation we express all Dirac and color structures encountered on the $|\Delta B|=1$ side via tree-level matrix elements of $|\Delta B|=2$ operators. This requires us to introduce additional operators

$$\tilde{Q} = \bar{s}_i \gamma^\mu (1 - \gamma^5) b_j \bar{s}_j \gamma^\mu (1 - \gamma^5) b_i, \quad Q_S = \bar{s}_i (1 + \gamma^5) b_i \bar{s}_j (1 + \gamma^5) b_j, \quad (10)$$

which equally enter the definitions of the evanescent $|\Delta B|=2$ operators (cf. [15, 16]).

An important subtlety that we have to address is the treatment of the $1/m_b$-suppressed operator $R_0$ [9, 12] defined as

$$R_0 = Q_S + \alpha_1 \tilde{Q}_S + \frac{1}{2} \alpha_2 Q.$$ \hspace{1em} (11)

Using Fierz identities and equations of motion on the level of the $|\Delta B|=2$ effective Hamiltonian one can show that in 4 dimensions

$$\langle Q_S \rangle^{(0)} + \langle \tilde{Q}_S \rangle^{(0)} + \frac{1}{2} \langle Q \rangle^{(0)} = O(1/m_b), \quad (12)$$

where $\langle \cdot \rangle^{(0)}$ denotes the tree-level matrix element of an operator. An important consequence of this relation is the fact that a $|\Delta B|=2$ operator basis made of $Q, Q_S$ and $\tilde{Q}_S$ leads to ambiguous results since in the matching one can always use Eq. (12) to shift arbitrary pieces of Wilson coefficients between the three operators. Choosing to work in a two-operator basis (e.g. $Q$ and $\tilde{Q}_S$) seemingly leads to correct matching coefficients, but only when IR divergences of the amplitudes are regularized using a fictitious gluon mass $m_g$ and not dimensionally. To obtain correct results when using dimensional regularization with $\varepsilon = \varepsilon_{UV} = \varepsilon_{IR}$ it is indeed necessary to include $R_0$ as defined in Eq. (11) to the operator basis. The point is that beyond tree-level the $1/m_b$-suppression of $R_0$ occurs only when IR divergences are regularized using $m_g$. In the case of dimensional IR regularization the unphysical evanescent piece of $R_0$, the so-called $E_{R_0}$, is not suppressed anymore [9, 16], which may potentially lead to incorrect matching coefficients. The practical recipe to circumvent this issue without writing down the explicit form of $E_{R_0}$ is to include the QCD correction factors $\alpha_{1,2}$ from Eq. (11) to the calculation when evaluating the matrix elements of $R_0$. Their task is to ensure that $R_0$ remains $1/m_b$-suppressed at each order in perturbation theory and thus to prevent a pollution of $H^{ab}(z)$ and $\tilde{H}^{ab}_S(z)$ with unwanted contributions from $R_0$. Notice that the results for $\alpha_{1,2}$ given in [9] are sufficient only for matching calculations at $O(\alpha_s)$, if one uses dimensional regularization to treat IR divergences. The fermionic (i.e. proportional to the number of quark flavors $n_f$) contributions to $O(\alpha_s^2)$ were published in [13], while in our work we extended this result to include also nonfermionic pieces.

We refer to [15, 16] for further technical details regarding our matching calculation. It should be noted, however, that our results were obtained as an expansion in $z = m^2_t/m_b^2$ up to $O(z)$. This can be regarded as sufficient for phenomenological purposes, given the good convergence of the $z$-expansion. In short, we evaluated all possible insertions of two $|\Delta B|=1$ operators (i.e. $Q_{1,2},$
QCD corrections to $B$-meson mixing at two loops and beyond

Vladyslav Shtabovenko

$Q_{3-6}$ and $Q_8$) up to two loops and tackled the insertions of two current-current operators $Q_{1,2}$ at three loops. In most cases the fermionic parts of these results were already known in the literature, which provided us with useful cross checks. The computationally challenging nonfermionic pieces that constitute a genuine result of our work are now publicly available in a computer-readable form for all the one- and two-loop matching coefficients. For the sake of clarity we summarize the current status quo in Table 1.

Table 1: Overview of the existing and new results required for the NNLO theory prediction of $\Delta \Gamma$, that were considered in this work. With “$n_f$-part only” we signify that the corresponding literature result provides only fermionic contributions, while “full” means that both fermionic and nonfermionic pieces are included.

3. Results

In [16] we published new theoretical predictions for the $B_s$-meson mixing observables that encompass our analytic two-loop results. While the numerical impact of the three-loop contribution is still in preparation, let us provide a brief overview of the numbers from [16].

Our starting point are the matching coefficients $H^{ab}(z)$ and $B_S^{ab}(z)$ with bottom and charm masses in the on-shell scheme, i.e. $z = \left(\frac{m_c^{\text{pole}}}{m_b^{\text{pole}}}\right)^2$. From there we switch to the $\overline{\text{MS}}$ scheme for $z$ by introducing $\tilde{z} = (m_c(m_b)/m_b(m_b))^2$. The choice of the renormalization scale in the running masses $\mu_c = \mu_b = m_b(m_b)$ is motivated by the vanishing of potentially large $z \log z$-terms [33] that occurs only for $\mu_c = \mu_b$. Having arrived at $H^{ab}(\tilde{z})$ and $B_S^{ab}(\tilde{z})$ that depend only on $\overline{\text{MS}}$ parameters, we still need to make a scheme choice for the $m_b^2$ prefactor in Eq. (8). Leaving it in the on-shell scheme defines our “pole” scheme [13, 14], while converting the prefactor to the $\overline{\text{MS}}$ mass yields our “$\overline{\text{MS}}$” scheme. As far as the nonperturbative matrix elements are concerned, we use the parametrization

$$\langle B_s | Q(\mu_2) | \overline{B}_s \rangle = \frac{8}{3} M_{B_s}^2 f_{B_s}^2 B_{B_s}(\mu_2) , \quad \langle B_s | \bar{Q}_S(\mu_2) | \overline{B}_s \rangle = \frac{1}{3} M_{B_s}^2 f_{B_s}^2 B_{S,B_s}(\mu_2).$$

(13)

Notice that although we employ lattice QCD results for the bag parameters $B_{B_s}$ and $B_{S,B_s}$, recent determinations [34] based on QCD/HQET sum rules [35–41], would have been an equally valid choice. Our numerical values for the input parameters are listed in Table 2. We set the renormalization scale $\mu_1$ of the $\Delta B = 1$ theory to $m_b(m_b)$ or $m_b^{\text{pole}}$ in the $\overline{\text{MS}}$ and pole schemes respectively. The $\Delta B = 2$ renormalization scale $\mu_2$ is, however, always fixed to $m_b^{\text{pole}}$. The evolution of the $\Delta B = 1$ matching coefficients $C_i$ from the high scale $\mu_0 = 165 \text{ GeV} \approx m_t(m_t)$ to $\mu_1$ is done using a private
code based on the results published in [46, 47]. We also include the effect of LO $1/m_b$-corrections to $\Delta \Gamma_s$ from [32].

Our results for the ratio $\Delta \Gamma_s/\Delta M_s$ using NLO analytic results for $M_{12}^s$ from [48] read

$$\frac{\Delta \Gamma_s}{\Delta M_s} = (4.70^{+0.32}_{-0.70} \text{scale} \pm 0.12 B_{BS} \pm 0.80_{1/m_b} \pm 0.05_{\text{input}}) \times 10^{-3} \quad (\text{pole}),$$

$$\frac{\Delta \Gamma_s}{\Delta M_s} = (5.20^{+0.01}_{-0.16} \text{scale} \pm 0.12 B_{BS} \pm 0.67_{1/m_b} \pm 0.06_{\text{input}}) \times 10^{-3} \quad (\text{MS}),$$

(14)

where the uncertainties are related to the variations of $\mu$ ("scale"), bag parameters ("$B_{BS}$"), matrix elements of the power-suppressed corrections ("$1/m_b$") as well as $\alpha_s(M_Z)$, $m_b(m_b)$, $m_c(3 \text{ GeV})$, $m_t^\text{pole}$ and the CKM parameters ("input"). As one can see, the $1/m_b$ corrections currently constitute the largest source of uncertainties, which necessitates the calculation of the corresponding contributions at NLO in $\alpha_s$. The scale uncertainties are equally nonnegligible, yet the final word on their importance can be said only upon incorporating the three-loop current-current contributions into our theoretical predictions.

As far as $a_{fs}^s$ is concerned, we find

$$a_{fs}^s = (2.07^{+0.10}_{-0.11} \text{scale} \pm 0.01 B_{BS} \pm 0.06_{1/m_b} \pm 0.06_{\text{input}}) \times 10^{-5} \quad (\text{pole}),$$

$$a_{fs}^s = (2.02^{+0.15}_{-0.17} \text{scale} \pm 0.01 B_{BS} \pm 0.05_{1/m_b} \pm 0.06_{\text{input}}) \times 10^{-5} \quad (\text{MS}).$$

(15)

Last but not least, using the experimental value for $\Delta M_s$ [42],

$$\Delta M_s^{\exp} = 17.7656 \pm 0.0057 \text{ ps}^{-1},$$

(16)

we can finally arrive at the predictions for $\Delta \Gamma_s$,

$$\Delta \Gamma_s^{\text{pole}} = (0.083^{+0.005}_{-0.012} \text{scale} \pm 0.002 B_{BS} \pm 0.014_{1/m_b} \pm 0.001_{\text{input}}) \text{ ps}^{-1},$$

$$\Delta \Gamma_s^{\text{MS}} = (0.092^{+0.002}_{-0.003} \text{scale} \pm 0.002 B_{BS} \pm 0.012_{1/m_b} \pm 0.001_{\text{input}}) \text{ ps}^{-1},$$

(17)
which agree with the experimental values within the (still large) uncertainties.

Due to space limitations and the fact that the above results will be soon superseded by our upcoming NNLO predictions, we would like to abstain from discussing these numbers in further details. The interested reader is referred to Section 5 of [16] which offers a detailed analysis of the subject.

4. Summary

We reported on the theoretical status of QCD corrections to the width difference $\Delta \Gamma_s$ in $B_s - \bar{B}_s$ oscillations, where our main effort was concentrated on the reduction of scale uncertainties at leading order in the $\Lambda_{\text{QCD}}/m_b$ expansion. The presented numerical results stem from our recent work [15, 16] where we computed all relevant matching coefficients at two-loop accuracy at $O(\alpha)$ and provided analytic results in form of computer-readable expressions. The last missing ingredient to reach the NNLO accuracy for $\Delta \Gamma_s$ is the three-loop contribution from current-current operator insertions. We are currently in the progress of updating our numerical analysis to include this piece (again at $O(\alpha)$) and expect to present preliminary numbers within the next months.

Acknowledgments

The author would like to thank Marvin Gerlach, Matthias Steinhauser and Ulrich Nierste for the collaboration on this project. We also acknowledge useful discussions with Artyom Hovhannisyan. This research was supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under grant 396021762 — TRR 257 “Particle Physics Phenomenology after the Higgs Discovery”. This report has been assigned preprint numbers TTP22-016 and P3H-22-031.
